## Summary

1. Models relating intake rate to food abundance and competitor density (generalized functional response models) can predict forager distributions and movements between patches, but we lack understanding of how distributions and small-scale movements by the foragers themselves affect intake rates.

**2.** Using a state-of-the-art approach based on continuous-time Markov chain dynamics, we add realism to classic functional response models by acknowledging that the chances to encounter food and competitors are influenced by movement decisions, and, vice versa, that movement decisions are influenced by these encounters.

**3.** We used a multi-state modelling framework to construct a stochastic functional response model in which foragers alternate between three behavioural states: searching, handling and moving.

**4.** Using behavioural observations on a molluscivore migrant shorebird (red knot, *Calidris canutus canutus*), at its main wintering area (Banc d'Arguin, Mauritania), we estimated transition rates between foraging states as a function of conspecific densities and densities of the two main bivalve prey.

5. Intake rate decreased with conspecific density. This interference effect was not due to decreased searching efficiency, but resulted from time lost to avoidance movements.

**6.** Red knots showed a strong functional response to one prey (*Dosinia isocardia*), but a weak response to the other prey (*Loripes lucinalis*). This corroborates predictions from a recently developed optimal diet model that accounts for the mildly toxic effects due to consuming *Loripes*.

7. Using model averaging across the most plausible multi-state models, the fully parameterized functional response model was then used to predict intake rate for an independent data set on habitat choice by red knot.

8. Comparison of the sites selected by red knots with random sampling sites showed that the birds fed at sites with higher than average *Loripes* and *Dosinia* densities, that is sites for which we predicted higher than average intake rates.

**9.** We discuss the limitations of Holling's classic functional response model which ignores movement and the limitations of contemporary movement ecological theory that ignores consumer–resource interactions. With the rapid advancement of technologies to track movements of individual foragers at fine spatial scales, the time is ripe to integrate descriptive tracking studies with stochastic movement-based functional response models.

**Key-words:** competition, continuous-time Markov chain, cryptic interference, diet, distribution, habitat choice, intake rate, movement ecology, predation, toxic prey

### Introduction

Fine-scale spatial movements of foragers are steered by encounters with food items, the presence of competitors and by the social benefits of living in a group. There is a growing body of literature on how the attractant forces of food interact with the opposing forces of conspecific attraction and repulsion (e.g. Folmer, Olff & Piersma 2010). Movement ecology is the emerging field in which these processes come together (Nathan et al. 2008). To make progress, we need a good understanding of what determines a forager's encounter rate with both its group members and its prey (Gurarie & Ovaskainen 2013). Functional response models link foragers to their prev and other foragers (Jeschke, Kopp & Tollrian 2002) and are a good starting point for modelling socially mediated and food-mediated movements (Avgar, Kuefler & Fryxell 2011).

In a substantial number of functional response models, the effects of prey density have been integrated with the effects of competitor density (i.e. the so-called generalized functional responses reviewed by van der Meer & Ens 1997). As stressed by van der Meer & Ens (1997), most of these models are phenomenological because they lack a mechanistic underpinning of the processes of prey and competitor encounter, rendering it difficult to use them as firm building blocks in follow-up studies. Unfortunately, ratio-dependent predation models, which have been claimed to offer an altered perspective on trophic ecology (Arditi & Ginzburg 2012), are of phenomenological nature too (Abrams 2014). But, note that even the few generalized functional response models that do mechanistically include competition have significant drawbacks. Most importantly, these models are built on the assumption that agonistic interactions are inevitable when two foragers meet. This rigid approach excludes the realistic possibility that foragers could avoid agonistic conflict situations by moving away from each other (Folmer, Olff & Piersma 2012). Recent empirical work has shown that socially foraging red knots (Calidris canutus) indeed avoid agonistic interactions (Bijleveld, Folmer & Piersma 2012). The time cost associated with this avoidance behaviour has been labelled 'cryptic interference' (Gyimesi, Stillman & Nolet 2010; Bijleveld, Folmer & Piersma 2012). Not unexpectedly, the few models that include avoidance behaviour do a better job in explaining variations in intake rate than models that ignore avoidance (Stillman, Goss-Custard & Caldow 1997; Stillman et al. 2000). However, in such models, foragers only move for reasons of competition, while there are also other reasons to change location.

Among these reasons are the benefits of staying in the vicinity of group members that may provide shelter (Wiersma & Piersma 1994), safety (Elgar 1989) and information (Couzin *et al.* 2005). Such benefits might indirectly affect food intake rates (Beauchamp 1998). For example, under experimental conditions in which the possibility for

physical interference was eliminated, starlings (*Sturnus vulgaris*) feeding close together showed enhanced food intake and foraging efficiency compared with birds feeding further apart (Fernández-Juricic, Siller & Kacelnik 2004). Efforts to embed socially mediated behaviour into functional response models are still at their infancy (Folmer, Olff & Piersma 2012). Not surprisingly, such models are yet to be developed and tested in the natural world.

The ways in which the presence (or absence) of food determines forager movements have been studied across wide range of organisms and spatial scales (e.g. Fryxell *et al.* 2008; Owen-Smith, Fryxell & Merrill 2010). Within contemporary movement ecology, there is much attention for how foragers should and do move through landscapes in search of food patches (Sims *et al.* 2008). Once in a patch and having encountered prey, it pays a forager to continue searching where it last found a prey (van Gils 2010), a strategy called 'area-restricted search' (Tinbergen, Impekoven & Franck 1967). Recently, there have been theoretical efforts to enforce the link between prey taxis to consumption rates (Chakraborty *et al.* 2007; Avgar, Kuefler & Fryxell 2011), but these studies have not yet received empirical scrutiny.

In this paper, we integrate food-driven and the socially driven aspects of movement into an empirically derived functional response model by means of continuous-time Markov chain modelling. This modelling approach allows the construction of realistic functional response models by explicitly taking into account the fact that finding food and running into competitors are sequential and stochastic events. In such models, foragers can alternate between behavioural states at any moment in time (hence 'continuous time'; van der Meer & Smallegange 2009), in which the instantaneous risk of switching to another state has 'Markov property', that is transition rates depend on the present behavioural state only and not on past states. Software to estimate statistical 'multi-state models' is available (e.g. Jackson 2011), which enables empirical analysis of transition rates between behavioural states as a function of food availability and the presence of group members (Smallegange & van der Meer 2010).

We develop realistic functional response models for the well-studied red knot (Piersma & van Gils 2011; Piersma 2012) on the basis of observed foraging behaviour. These models are then used to predict spatial distributions on the basis of measured food distributions. We start off by constructing a Markov chain functional response model in which foragers alternate between the behavioural states 'searching for food', 'handling food' and 'moving without searching'. Next, we fit this model to focal sampling data collected on 1242 individual free-ranging red knots at their main wintering area in Banc d'Arguin (Mauritania), in which transition rates between searching, handling and moving are related to prey and conspecific densities. The best models are then used to make spatially explicit predictions on (interference-free) intake rate with an independent data set on food abundance, collected in another year. The predictive power of the models is investigated by relating the exact positions of 5666 individual red knots to predicted (interference-free) intake rates.

# CONTINUOUS-TIME MULTI-STATE MARKOV CHAIN MODEL

In the model, graphically depicted in Fig. 1, a forager can be in three mutually exclusive behavioural states (handling H, searching S and moving M), with five possible transitions between these states. From the searching state, a forager can either switch to the handling or the moving state. The rate at which a searching forager 'switches' to the handling state is better known as prey encounter rate and is symbolized in our model by  $\beta$ . The rate at which a searching forager decides to move on is given by  $\delta$ . Thus, the total rate of a searching forager to stop searching, either due to a prey encounter or a decision to move on, is given by  $\beta + \delta$ . The inverse of this sum is the average length of a search bout. The rate at which a handling forager switches back to the searching state is given by  $\alpha$ , while the rate of switching to the moving state is given by μ. Finally, a moving forager can only go back to the searching state, and the rate at which this occurs is given by  $\gamma$ . A moving forager cannot find a prey, and hence, transitions from moving to handling do not exist.

The following set of differential equations describes the dynamics in the number of handling (H), searching (S) and moving (M) foragers:

$$\frac{\mathrm{d}H}{\mathrm{d}t} = \beta S - \alpha H - \mu H \qquad \text{eqn 1}$$

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \alpha H - \beta S + \gamma M - \delta S \qquad \text{eqn } 2$$

$$\frac{\mathrm{d}M}{\mathrm{d}t} = \delta S - \gamma M + \mu H \qquad \text{eqn 3}$$

At equilibrium, the number of individuals in each state is constant, which implies that each differential equation can be set to zero. This allows the equilibria  $H^*$ ,  $S^*$  and  $M^*$  to be calculated:

**Fig. 1.** Red knots show three behavioural states (searching S; handling H; moving M), between which they alternate while foraging (Greek symbols indicate transition rates). Note that the transition from moving to handling does not exist, that is handling is always preceded by searching.

$$H^* = \frac{\beta S^*}{\alpha + \mu} \qquad \qquad \text{eqn 4}$$

$$S^* = \frac{\alpha H^* + \gamma M^*}{\beta + \delta} \qquad \text{eqn 5}$$

$$M^* = \frac{\delta S^* + \mu H^*}{\gamma} \qquad \text{eqn 6}$$

Since the total number  $F^*$  of foragers can be expressed as  $F^* = H^* + S^* + M^*$ , the proportion of birds in the searching state at equilibrium can be written as (after substituting eqn 4 for  $H^*$  in eqn 6):

$$\frac{S^*}{F^*} = \frac{(\alpha + \mu)\gamma}{(\alpha + \beta + \mu)\gamma + (\alpha + \mu)\delta + \mu\beta}$$
 eqn 7

The multiplication of  $S^* / F^*$  with the transition rate  $\beta$  from searching to handling (i.e. the encounter rate with prey while searching) gives the per capita intake rate (van der Meer & Smallegange 2009). In the STATISTICS section below, we explain how we linked covariates to transition rates.

#### Materials and methods

All data were collected in the Parc National du Banc d'Arguin, around the small fishery village of Iwik (Fig. 2a; Leyrer *et al.* 2012; van den Hout *et al.* 2014). To develop the multi-state functional response models and to test how well they predict foraging distributions, data on intake rate and on foraging distributions were collected during two separate expeditions. Behavioural data, which formed the basis for the Markov chain modelling, were collected in January–February 2008. Spatial distributions were collected in March-April 2007. Prey densities were sampled in both years.

#### INTAKE RATE PROTOCOLS (2008)

Observations on intake rates were carried out at three different sites in our study area (Fig. 2a). We returned to each site every third day to carry out observations. At two sites (site D and I), the observers sat on top of an aluminium scaffolding tower (LWH =  $2 \times 1 \times 2$  m); at the other site (site A), observations were carried out from a nearby dune. In total, 5 days were spent at site A (covering 7 low-tide periods), 5 days at site D (5 low-tide periods) and 6 days at site I (6 low-tide periods). In total, we carried out observations on 1242 individual birds (411 at site A; 324 at site D; 507 at site I).

Using  $20-60 \times$  spotting scopes, we applied focal sampling by selecting focal individuals haphazardly. Each protocol comprised the period between two consecutive prey captures (mean  $\pm$  SD duration =  $39.0 \pm 42.0$  s). During this interval, behaviour was recorded using a voice recorder (Philips Digital Voice Tracer 7655, Atlanta, GA, USA) and was categorized into nine different classes (searching, handling, walking without searching [i.e. moving], looking up, preening, chasing or being chased, flying, washing, drinking). Recorded observations were digitized using the freeware package ETHOLOG (Ottoni 2000). To avoid unwieldy models, we only considered transitions between the three most frequent behaviours (searching, handling and moving), and

#### 4 J. A. van Gils et al.

Fig. 2. (a) Map of our study area around the Iwik village (19°53' N; 16°18' W), showing observation towers A-I and the observation area around each of them. Colours represent the NDVI and are indicative of seagrass coverage (based on a Landsat 5 image taken at 21 August 2007). Light grey shading indicates the mainland; darker grey represents the sea. (b) Around each tower, exemplified here for tower D, an annulus was divided into 128 'bird sections' (bordered by thin lines) and 16 'benthos sections' for stratification (bordered by thick lines); each benthos section had two randomly located benthos stations (labelled dots), with two benthos samples taken at each station.

excluded transitions between the other six behaviours (which together made up only 6% of the total time budget). Using numbered wooden sticks, we divided an annulus (outer radius 200 m. inner radius 100 m) around the observation tower into 128 equally sized 'bird sections' (Fig. 2b). At site A, the observational arena comprised half an annulus (outer radius 100 m, inner radius 50 m), which was divided into 20 sections. The section in which the focal bird fed, together with the estimated distance from tower, enabled us to determine the position of the focal bird, which was used to assign a prey density estimate to each observation (see below). The total number of red knots, including the focal bird, present in the focal bird's section was counted immediately after the protocol ended, which was used as our measure of knot density. Before the analysis, the number of red knots per plot at site A (589 m<sup>2</sup> per plot) was multiplied by 1.25 to make them comparable to the densities at the other two sites (736 m<sup>2</sup> per plot). All observations were carried out by JAvG and HG. To prevent possible observer bias, both observers carried out simultaneous observations on the same birds during the 2 days preceding data collection.

#### **RED KNOT DISTRIBUTION (2007)**

In 2007, we mapped the positions of individual red knots on seven different tidal flats in our study area (sites B-H; Fig. 2a), spending a single day at each site (usually covering a single low-tide period, but sometimes two half low-tide periods). Again we worked from a single scaffolding tower, which we relocated between observation days. As described above, an observation area comprised an annulus around the tower (outer radius 200 m, inner radius 100 m), with the annulus split up into 128 equally sized and shaped parts using poles placed at known coordinates (Fig. 2b).

Every half hour a photo was taken of each section, using a DSLR-camera (6·1 MP) with a 300-mm lens and 1·4 teleconvertor attached to it. Using this setup, one bird section fitted exactly into one photograph, while allowing recognition of individual bird species. With 64 half hours across all seven sites, we obtained a total of 8192 photos. The photographs were loaded into a GIS where the poles (indicating the section corners) and all individual birds were marked and given relative coordinates.

The points describing the locations of the poles and birds were stored in a vector file. As the poles' geographical and relative coordinates were known, we were able to calculate the birds' geographical coordinates on the basis of principles of projective geometry for which we used MATLAB R2011a (MathWorks, Natick, MA, USA). We first calculated the parameters of the projective transformation on the basis of the poles' relative and geographical coordinates. Then the projection parameters were used to project the birds' relative positions to geographical coordinates. In total, we calculated the positions of 5666 individual red knots in this way.

#### PREY DENSITY AND INTERPOLATION

In both years, prey densities were estimated by taking sediment core samples at a number of stations inside the annulus around each tower. We divided the annulus around each tower into 16 equally sized 'benthos sections' where benthos was sampled (the half annulus at site A used in 2008 was divided into three 'benthos sections'). In each benthos section, we randomly selected two locations (Fig. 2b). At each location, two cores were taken. The distance between the cores at one location was 1 m in a random direction (to the benefit of estimating the autocorrelation function at short distances required for kriging, see below). In total, we collected 448 benthos samples in 2007 ( $7 \times 16 \times 2 \times 2$ ) and 140 samples in 2008 ( $2 \times 16 \times 2 \times 2 + 1 \times 3 \times 2 \times 2$ ).

Following procedures published elsewhere (van Gils et al. 2013), samples were taken with a sediment core with a diameter of 15 cm to a depth of 20 cm. To distinguish prey that were accessible to red knots from those that were not, we separated the top (0-4 cm) from the bottom layer (4-20 cm; red knots have bills of 3.5-4.0-cm length) and sieved both layers over a 1-mm mesh. In the laboratory, samples were sorted and each specimen was identified to species or genus level. Lengths were determined to the nearest 0.1 mm. As just two prey species at Banc d'Arguin dominate the food supply and diet of red knot (van Gils et al. 2012, 2013; Onrust et al. 2013; van den Hout et al. 2014), we included only these two species in the analyses (Dosinia isocardia; Loripes lucinalis). Dosinia longer than 13.2-mm were excluded from the analyses, as red knots ingest their prey whole and are therefore gape-width limited in their diet choice (Zwarts & Blomert 1992).

To estimate available Loripes and Dosinia densities at the individual bird positions (be it a focal bird in the 2008 intake rate protocols or a 'photo bird' in the 2007 distributional analysis), the sampled densities were interpolated by means of universal kriging. Because seagrass cover correlates with both Loripes and Dosinia density (Honkoop et al. 2008; van der Heide et al. 2012). and because Normalized Difference Vegetation Index (NDVI) is a good proxy for seagrass coverage in our study area (Folmer et al. 2012), we used NDVI and NDVI<sup>2</sup> as auxiliary predictors of prey density. NDVI was derived from an image taken on 21 August 2007 at 11:25 AM GMT (the date most intermediate to both expeditions) by the Landsat 5 TM (USGS, Reston, VA, USA) satellite. The image was taken 1:25 h before local low-tide (using the Dakar tidal chart and assuming a 5-h delay in Iwik; Wolff & Smit 1990), with an average cloud cover of 10% (but being 0% for our study area). Following standard procedures (Kriegler et al. 1969), NDVI was calculated as (NIR-red)/ (NIR+red), with the NIR reflection given by band 4 and the red reflection given by band 3 (both at a 30 by 30-m resolution; Fig. 2).

The best regression models for the deterministic parts of universal kriging were obtained as follows: prey densities were  $\log_{e^-}$  transformed to normalize the distributions. We added 1 to the arguments to avoid taking the logarithm of zero (which we subtracted after back-transforming the interpolated densities). We estimated the full model which included NDVI and NDVI<sup>2</sup> as predictors and the nested sub-models (i.e. only NDVI or NDVI<sup>2</sup> as a predictor). For the deterministic part in universal kriging, we used the model with the lowest AIC value (results are given in Table S1, Supporting Information). For kriging, we used the R package *automap* (Hiemstra *et al.* 2008), which builds on package *gstat* (Pebesma 2004) and enables automatic interpolation. In this way, the regression and geostatistical models may differ between tidal flats. Each individual red knot was assigned prey density values by spatially merging the benthos and bird distributions.

#### STATISTICS

Multi-state models were fitted with R (R Core Team 2013) using the msm package (Jackson 2011), which enables multi-state models to be fitted to longitudinal data (i.e. observations of state collected on the same subjects at multiple points in time). The msm package is able to estimate transition rates without knowing the exact moments of state changes; however, in our case, we knew these exact moments, which obviously improves the accuracy of estimating transition rates. We explored how these rates covaried with available Dosinia density, available Loripes density, summed density of available Dosinia and Loripes, and red knot density, testing for all possible combinations and interactions (but excluding combinations of summed prey density on the one hand and Dosinia or Loripes density on the other hand, since summed prey density is the sum of Dosinia and Loripes density). In the msm package, these effects were tested using the proportional hazard model (Marshall & Jones 1995) as expressed below, taking transition rate  $\beta$  from searching to handling as an example:

$$\beta_i = \beta_{0,i} \exp(b_1 X_{1,i} + b_2 X_{2,i} + \dots + b_k X_{k,i})$$
 eqn 8

In this model,  $\beta_i$  is the transition rate  $\beta$  of observation *i* on an individual's searching state,  $\beta_{0,i}$  is this observation's baseline transition rate (i.e.  $\beta_i = \beta_{0,i}$  when covariates set to 0),  $X_{1,i} \dots X_{k,i}$  are k covariates and  $b_1 \ \ldots \ b_k$  their statistical effects (note that the model has the same structure for transition rates  $\alpha$ ,  $\gamma$ ,  $\delta$  and  $\mu$ ). The model is proportional in the sense that effects of the covariates are multiplicative with respect to baseline rates (e.g. each unit increase in covariate  $X_1$  would result in a proportional scaling of transition rate  $\beta$ ). Further note that Markov models require individual bout lengths (i.e. the inverse of transition rate) to be exponentially distributed, a requirement for which we tested using the Cramér-von Mises test (using R package exptest; Pusev & Yakovlev 2011). Models were selected on the basis of Akaike's Information Criterion (AIC; Burnham & Anderson 2002). Particularly, all models were ranked in order of increasing AIC values, with the model showing the lowest AIC value considered as the best model. Following Burnham & Anderson (2002), models with  $\Delta AIC < 2$  relative to the best model were also considered. All models were included for model averaging (including those with  $\Delta AIC \ge 2$ ), using each model's AIC weight as a weighing factor.

We used bagplots to explore the spatial distribution of red knots in relation to prey densities (using the *aplpack* package in r; Wolf & Universität Bielefeld 2012). Bagplots are the bivariate generalization of the well-known univariate boxplot, with the 50% most central data shown by a bag-shaped surface (Rousseeuw, Ruts & Tukey 1999).

#### Results

#### FUNCTIONAL RESPONSE

The frequency distribution of the durations of search bouts did not deviate from the exponential distribution (Fig. 3a; Cramér–von Mises test  $\omega_n^2 = 1.93$ ; n = 2109; P = 1). This was also the case for the distribution of handling times (Fig. 3b;  $\omega_n^2 = 13.38$ ; n = 1242; P = 1) and moving bouts (Fig. 3c;  $\omega_n^2 = 2.90$ ; n = 929; P = 1).

Two models explaining interstate transition rates were about equally plausible. The best model (AIC weight = 0.52) included all three main effects (the densities of *Dosinia*, *Loripes* and red knots) and one interaction (between *Dosinia* and *Loripes* densities; Table 1). The second best model (AIC weight = 0.43), included *Dosinia* and red knot density only. All the other models were less supported ( $\Delta$ AIC > 2) and therefore considered unlikely.

In both of the plausible models, Dosinia density had positive effects on  $\alpha$ ,  $\beta$  and  $\gamma$  (Tables 2–3). This means that at higher (available) Dosinia densities, red knots were: (i) more likely to resume searching after having found and handled a prey  $(\alpha)$ ; (ii) more likely to shift to handling state while searching or stated more simply, found prey at a higher rate  $(\beta)$ ; and (iii) returned to the searching state at higher rates after having moved  $(\gamma)$ . *Loripes* density had an effect on  $\beta$ , which can be seen by considering the main effect and the interaction with Dosinia density (Table 2). Particularly, the main effect was positive but non-significant, and the interaction was negative (and significant). The results imply that prey encounter rate  $\beta$  increased with *Loripes* density at low *Do*sinia density but showed no response to Loripes density at higher Dosinia densities (also refer to model-averaged model fits in Fig. 4). Red knot density affected transition rates  $\alpha$ ,  $\mu$ ,  $\delta$  and  $\gamma$ . After handling prey in dense flocks, red knots were more likely to start moving (positive effect

on  $\mu$ ) and less likely to return to the searching state (negative effect on  $\alpha$ ). Also when searching at high red knot densities, they were more likely to give up searching and move on ( $\delta$ ). In addition, once moving through dense flocks, red knots were less likely to get back into their searching mode ( $\gamma$ ).

#### RED KNOT DISTRIBUTION

The majority of the 5666 individual red knots selected feeding sites that had higher available *Dosinia* and available *Loripes* densities (Fig. 4: small dark grey bag) than average densities (Fig. 4: large light grey bag based on kriged prey densities at benthos sites). Feeding sites contained higher densities of *Dosinia* (t = 3.59, d.f. = 233.5, P < 5e-4) and *Loripes* (t = 4.39, d.f. = 234.7, P < 5e-05) than our benthos sites). By feeding at relatively high prey densities, the red knots obtained relatively high intake rates [solid lines in Fig. 4, which are interference-free intake rates as predicted by the model-averaged multi-state model in which  $\log_e$  (red knot density) = 0].

#### Discussion

#### FUNCTIONAL RESPONSE

The Markov chain modelling approach that we used has yielded important insights in the dynamical processes affecting prey intake rates and movements by red knots. We start with a discussion on the effects of conspecific density on foraging behaviour. The local density of red knots affected multiple behavioural transitions, which determine the functional response. Although interference is often assumed to reduce searching efficiency directly (e.g. see citation classic by Hassell & Varley 1969), it was not observed in our study (no effect of conspecific density on  $\beta$ ). Instead, the effects of interference appeared more subtle via a reduction of the transition rates to searching from handling ( $\alpha$ ) and moving ( $\gamma$ ). Stated otherwise, the more conspecifics surround a given red knot, the smaller

Fig. 3. Frequency distributions of the durations (s) of the three behavioural states: (a) searching, (b) handling and (c) moving. Each frequency distribution complies with the exponential distribution, with lines giving maximum-likelihood fits (yielding mean  $\pm$  SD rates of 0.059  $\pm$  0.001 s<sup>-1</sup> for searching; 0.552  $\pm$  0.016 s<sup>-1</sup> for handling; 0.424  $\pm$  0.014 s<sup>-1</sup> for moving).

AIC = 26 862.97. The best models with  $\Delta$ AIC < 2 are given in bold. The best model's AIC is given below the table; Np denotes the number of model parameters.

the likelihood that this bird would commence searching. The density of conspecifics in the vicinity increased the transition rates from handling to moving and from searching to moving ( $\mu$  and  $\delta$ , respectively). These conspecific density effects can be interpreted as movement behaviour to avoid or reduce possible direct interference effects, a phenomenon coined 'cryptic interference' (Gyimesi, Stillman & Nolet 2010; Bijleveld, Folmer & Piersma 2012).

Enter the effects of prey density. Starting with *Dosinia*, higher densities of this prey stimulated the transitions to searching, both when handling ( $\alpha$ ) and when moving ( $\gamma$ ). These effects can be interpreted as behaviour leading to area-restricted search (Barraquand & Benhamou 2008) and would not have been detected if we had tested data against the more static classic functional response models (see below). *Dosinia* also had a positive effect on  $\beta$ . This effect is expected, since  $\beta$ , the transition rate between searching and handling, is equivalent to prey encounter rate (van der Meer & Smallegange 2009), which increases with prey density in any functional response model (Jeschke, Kopp & Tollrian 2002). It came as a surprise that the coefficient was smaller than one. A coefficient of one is expected under Holling's assumption of a searching efficiency that does not vary with prey density (refer to eqn. 8 in which  $\beta$  would then be a linear function of prey density and  $\beta_0$  would be searching efficiency; also see discussion below). A coefficient smaller than one means reduced searching efficiencies at higher prey densities, a phenomenon likely due to higher rates of 'invisible' prey rejection at higher prey densities (due to a digestive constraint red knots are expected to reject an increasing proportion of *Dosinia* at high densities; van Gils *et al.* 2013). As prey rejections may occur before prey are lifted to the sediment surface, we have likely missed prey rejections, thereby underestimating searching efficiency at higher prey densities.

Only at low prey densities did more Loripes increase intake rate (model fits in Fig. 4 and Table 2). In the light of our recent findings, this result did not surprise us. Although Loripes with its high flesh-to-shell ratios may seem the ideal prey, it is not. This is because an endosymbiosis with chemoautotrophic sulphur-oxidizing bacteria (van der Geest et al. 2014) makes Loripes, once ingested by red knots, mildly toxic (Oudman et al. 2014). Red knots suffer from diarrhoea when only eating Loripes, leading to dehydration and reduced feeding rates; the birds face this toxin constraint at available Loripes of at least 50 m<sup>-2</sup> (dashed horizontal line Fig. 4 based on parameters in van Gils et al. 2013). Hence, below this critical Loripes density, intake rate should increase with both Loripes and Dosinia density, whereas above this critical Loripes density, red knots should reject an increasing proportion of Loripes and intake rates should level off with Loripes density and only increase with Dosinia (as stated above, also Dosinia will be rejected, but at a much lower rate). This is the key prediction of the recently published optimal diet model that takes account of Loripes' toxicity (TDRM; van Gils et al. 2013). As illustrated by the lines of equal intake rate predicted by the model-averaged multi-state model (Fig. 4), it corresponds nicely with the intake rates found in this study. These lines shift from being diagonal (i.e. more or less equal intake rate on Dosinia and Loripes) to vertical (i.e. additional increase in intake due to Dosinia only) when going from low to high Loripes densities in the environmental bagplot.

#### RED KNOT DISTRIBUTION

Red knots selected sites with relatively high densities of both *Dosinia* and *Loripes* (Fig. 4). That they selected for high *Loripes* densities may be surprising in the light of *Loripes*' toxicity effects. However, 2007 was a relatively poor year in terms of *Dosinia* densities, and red knots would not have been able to survive without the inclusion of *Loripes* in their diet (van Gils *et al.* 2013). Indeed, dropping analyses showed that in 2007 red knots included both *Loripes* and *Dosinia* in their diet, for about 60% and 40%, respectively (van Gils *et al.* 2013; Onrust *et al.* 2013). Combining these diet compositions with the fitted

numerical intake rates (*c*.  $0.025 \text{ s}^{-1}$ ) yields energy intake rates of 0.1-mg ash-free dry mass per second (taking species-specific energy values for 2007 from van Gils *et al.* 2013).

#### GENERAL IMPLICATIONS

Movement ecology is a rapidly expanding field in which landscape ecology, animal behaviour and statistical physics come together, empirically encouraged by the ongoing miniaturization of animal tracking devices at ever higher resolutions (Nathan *et al.* 2008; Giuggioli & Bartumeus 2010). Although optimal foraging theory may be considered as one of the theoretical backbones of this exciting scientific proliferation, we are yet at the infancy to link forager movement with processes affecting prey encounter rate. The functional response is the fundamental link between a forager's intake rate and its prey. It therefore makes perfect sense to integrate movement decisions with the two basic behavioural components underlying any functional response, that is searching and handling events. By doing so, movement processes have naturally emerged from our modelling exercise, that is area-restricted search (transition rates to/from movement affected by food density) and cryptic interference (transition rates to/from movement affected by competitor density). Without the explicit consideration of movement behaviour, these subtle foraging behaviours would probably not have been unveiled.

The flexible Markov chain modelling framework allowed us to explore what outcome we would have

**Fig. 4.** State space of the available *Loripes* densities against available *Dosinia* densities in 2007 in the environment (larger light grey 'bag') and at the sites selected by individual red knots (smaller dark grey 'bag'). These bagplots include the most central half of the data. Letters indicate the average prey densities at the knot-selected sites for each tower, with the size of the letter indicative for the number of individuals. Three curved lines are lines of equal intake rate (s<sup>-1</sup>) as predicted by the model-averaged multi-state model (these are interference-free intake rates by setting red knot density to 1). Dashed horizontal line gives minimal *Loripes* density at which red knots face their toxin constraint (see Discussion).

obtained if we had ignored the movement state in our models by setting covariate effects on transitions to ( $\delta$ and  $\mu$ ) and from ( $\gamma$  and  $\epsilon$ ) movement to zero (i.e. still allowing for movement, but without allowing covariate effects on transitions to and from movement state). The results are striking (Tables S2-S4, Supporting Information). Although the two most plausible models are still the same (albeit that the order is reversed; Table S2, Supporting Information), the effects of prey density in the full model become non-significant (Table S4, Supporting Information). The only significant effect remaining is the negative effect of red knot density on  $\alpha$ , the transition from handling to searching (Table S4, Supporting information). Hence, by ignoring spatial movements, we would have overlooked the subtle effects of Loripes density and its interaction with Dosinia density on red knot intake rate.

More subtlety is lost if we would, besides ignoring movement, stick to the rigid assumptions of Holling's disc equation, namely that both searching efficiency and handling time are not affected by prey density (Holling 1959; Piersma *et al.* 1995). In that case, the only plausible model remaining is the model in which red knot density and the *summed* densities of *Dosinia* and *Loripes* feature (Tables S5–S6, Supporting Information). Hence, under these restricted parameter settings, we would have concluded that prey density affects intake rate, but we would not have detected the differential roles of *Dosinia* and *Loripes*.

Clearly, there are many benefits to include movement as a behavioural element. Similarly, adding realistic and detailed consumer behaviour to movement analyses is of equally great value. Until now, one of the pillars in movement ecology consisted of models featuring solitary, uninformed foragers (Sims et al. 2008). In the real world, however, foragers tend not to feed alone (Giraldeau & Caraco 2000) and usually have basic information about food distributions in their environment (Olsson et al. 1999; van Gils et al. 2006; Bijleveld et al. 2014). Therefore, foragers will tweak their movements in response to encounters with conspecifics and food. Our work shows how real-world foragers do this. We hope that our effort to integrate movement behaviour and consumer-resource theory adds realism to the exciting fields of movement ecology and foraging theory.

#### Acknowledgements

We thank Parc National du Banc d'Arguin (PNBA) for their hospitality, the hosting of our presence and the permission to work in and from the Iwik scientific station. Lemhaba ould Yarba made the logistic arrangements. Joop van Eerbeek, Erik J. Jansen, Han Olff and El-Hacen Mohamed El-Hacen helped collecting and sorting benthos samples. Valuable comments on the manuscript were given by Allert Bijleveld, Jaap van der Meer, Ola Olsson, Thomas Oudman, Isabel M. Smallegange, an anonymous referee and by the 'literature club' of the Centre for Integrative Ecology during JAvG's sabbatical at Deakin University. Dick Visser polished the figures. This work is supported by an NWO WOTRO Integrated Programme grant (W.01.65.221.00) to TP, an NWO travel grant (R 84-639) to EOF, and an NWO VIDI grant (864.09.002) to JAvG.

### **Supporting Information**

Additional Supporting Information may be found in the online version of this article.

**Table S1.**  $\Delta$ AIC derived from regressions used for universal kriging of prey densities.

**Table S2.** Ranking of multi-state models in which covariate effects on transitions to and from the movement state are set to zero.

**Table S3.** Regression coefficients of the most plausible multi-state model (i.e. upper model in Table S2), in which covariate effects on transitions to and from the movement state are set to zero (with 95% c.i. given in brackets).

**Table S4.** Regression coefficients of the second most plausible multi-state model (i.e. second model in Table S2), in which covariate effects on transitions to and from the movement state are set to zero (with 95% c.i. given in brackets).

**Table S5.** Ranking of multi-state models in which covariate effects on transitions to and from the movement state are set to zero and in which Holling's assumptions about constancy of searching efficiency and handling time are fulfilled.

**Table S6.** Regression coefficients of the most plausible multi-state model (i.e. upper model in Table S5), in which covariate effects on transitions to and from the movement state are set to zero and in which Holling's assumptions on a constant searching efficiency and a constant handling time are fulfilled (with 95% c.i. given in brackets).
